

Combining Information Across Diverse Sources via Confidence Distributions: the II-CC-FF Paradigm

Nils Lid Hjort

Department of Mathematics, University of Oslo

JSM, Chicago, 2nd August 2016

The problem: Combining information

Suppose ψ is a **parameter of interest**, with data y_1, \dots, y_k from sources $1, \dots, k$ carrying information about ψ . **How to combine** these pieces of information?

Standard (and simple) example: $y_j \sim N(\psi, \sigma_j^2)$ are independent, with known or well estimated σ_j . Then

$$\hat{\psi} = \frac{\sum_{j=1}^k y_j / \sigma_j^2}{\sum_{j=1}^k 1 / \sigma_j^2} \sim N\left(\psi, \left(\sum_{j=1}^k 1 / \sigma_j^2\right)^{-1}\right).$$

Often additional variability among the ψ_j . Would e.g. be interested in assessing both parameters of $\psi \sim N(\psi_0, \tau^2)$.

We need **extended methods** and partly **new paradigms** for handling cases with **very different types** of information.

Plan

General problem formulation:

Data y_j source j carry information about ψ_j . Wish to assess overall aspects of these ψ_j , perhaps for inference concerning some $\phi(\psi_1, \dots, \psi_k)$.

- A Confidence distributions
- B Previous CD combination methods (Singh, Strawderman, Xie, Liu, Liu)
- C A different II-CC-FF paradigm, via steps Independent Inspection, Confidence Conversion, Focused Fusion, and confidence-to-likelihood operations
- D1 Example 1: Effective population size for cod
- D2 Example 2: Olympic unfairness
- E Concluding remarks

A: Confidence distributions

For a parameter ψ , suppose data y give rise to confidence intervals, say $[\psi_{0.05}, \psi_{0.95}]$ at level 0.90, but also for other levels. These are converted into a full **distribution of confidence**, with

$$[\psi_{0.05}, \psi_{0.95}] = [C^{-1}(0.05, y_{\text{obs}}), C^{-1}(0.95, y_{\text{obs}})],$$

etc. Here $C(\psi, y)$ is a cdf in ψ , for each y , and

$$C(\psi_0, Y) \sim \text{unif} \quad \text{at true value } \psi_0.$$

Very useful, also qua graphical summary: the **confidence curve**

$$\text{cc}(\psi) = |1 - 2 C(\psi, y_{\text{obs}})|,$$

with $\text{cc}(\psi) = 0.90$ giving the two roots $\psi_{0.05}, \psi_{0.95}$, etc.

An extensive theory is available for CDs, cf. **Confidence, Likelihood, Probability**, Schweder and Hjort (CUP, 2016).

B: Liu, Liu, Singh, Strawderman, Xie et al. methods

Data y_j give rise to a CD $C_j(\psi, y_j)$ for ψ . Under true value, $C_j(\psi, Y_j) \sim \text{unif.}$ Hence $\Phi^{-1}(C_j(\psi, Y_j)) \sim N(0, 1)$, and

$$\bar{C}(\psi) = \Phi\left(\sum_{j=1}^k w_j \Phi^{-1}(C_j(\psi, Y_j))\right)$$

is a combined CD, if the weights w_j are nonrandom and $\sum_{j=1}^k w_j^2 = 1$.

This is a **versatile and broadly applicable** method, but with some drawbacks: (a) **trouble** when estimated weights \hat{w}_j are used; (b) **lack of full efficiency**. In various cases, there are better CD combination methods, with higher **confidence power**.

Better (in various cases): sticking to **likelihoods** and **sufficiency**.

CD combination via confidence likelihoods

Combining information, for inference about **focus parameter**

$\phi = \phi(\psi_1, \dots, \psi_k)$: **General II-CC-FF paradigm** for combination of information sources:

II: Independent Inspection: From data source y_j to estimate and intervals, yielding a CD:

$$y_j \implies C_j(\psi_j).$$

CC: Confidence Conversion: From the confidence distribution to a confidence log-likelihood,

$$C_j(\psi_j) \implies \ell_{c,j}(\psi_j).$$

FF: Focused Fusion: Use the **combined confidence log-likelihood**

$\ell_c = \sum_{j=1}^k \ell_{c,j}(\psi_j)$ to construct a CD **for the given focus** $\phi = \phi(\psi_1, \dots, \psi_k)$, perhaps via profiling, median-Bartlettting, etc.:

$$\ell_c(\psi_1, \dots, \psi_k) \implies \bar{C}_{\text{fusion}}(\phi).$$

FF is also the (focused) **Summary of Summaries** operation.

Carrying out **steps II, CC, FF** can be hard work, depending on circumstances. The **CC step** is sometimes the hardest (**conversion** of CD to log-likelihood). The simplest method is **normal conversion**,

$$\ell_{c,j}(\psi_j) = -\frac{1}{2}\Gamma_1^{-1}(cc_j(\psi_j)) = -\frac{1}{2}\{\Phi^{-1}(C_j(\psi_j))\}^2,$$

but **more elaborate methods** may typically be called for.

Sometimes **step II** needs to be based on summaries from other work (e.g. from point estimate and a .95 interval to approximate CD).

With **raw data and sufficient time** for careful modelling, **steps II and CC** may lead to $\ell_{c,j}(\psi_j)$ directly. Even then having individual CDs for the ψ_j is informative and useful.

Illustration 1: Classic meta-analysis.

II: Independent Inspection: Statistical work with data source y_j leads to $\hat{\psi}_j \sim N(\psi_j, \sigma_j^2)$; $C_j(\psi_j) = \Phi((\psi_j - \hat{\psi}_j)/\sigma_j)$.

CC: Confidence Conversion: From $C_j(\psi_j)$ to $\ell_{c,j}(\psi_j) = -\frac{1}{2}(\psi_j - \hat{\psi}_j)^2/\sigma_j^2$.

FF: Focused Fusion: With a common mean parameter across studies: Summing $\ell_{c,j}(\psi_j)$ leads to classic answer

$$\hat{\psi} = \frac{\sum_{j=1}^k \hat{\psi}_j/\sigma_j^2}{\sum_{j=1}^k 1/\sigma_j^2} \sim N\left(\psi, \left(\sum_{j=1}^k 1/\sigma_j^2\right)^{-1}\right).$$

With ψ_j varying as $N(\psi_0, \tau^2)$: then $\hat{\psi}_j \sim N(\psi_0, \tau^2 + \sigma_j^2)$. CD for τ :

$$C(\tau) = \Pr_{\tau}\{Q_k(\tau) \geq Q_{k,\text{obs}}(\tau)\} = 1 - \Gamma_{k-1}(Q_{k,\text{obs}}(\tau)),$$

with $Q_k(\tau) = \sum_{j=1}^k \{\hat{\psi}_j - \bar{\psi}(\tau)\}^2/(\tau^2 + \sigma_j^2)$. There is a positive confidence probability for $\tau = 0$. CD for ψ_0 : based on t-bootstrapping and

$$t = \{\bar{\psi}(\hat{\tau}) - \psi\}/\kappa(\hat{\tau}).$$

Illustration 2: Let $Y_j \sim \text{Gamma}(a_j, \theta)$, with known shape a_j .

II: Independent Inspection: Optimal CD for θ based in Y_j is $C_j(\theta) = G(\theta y_j, a_j, 1)$.

CC: Confidence Conversion: From $C_j(\theta)$ to $\ell_{c,j}(\psi_j) = -\theta y_j + a_j \log \theta$.

FF: Focused Fusion: Summing confidence log-likelihoods, $\tilde{C}_{\text{fusion}}(\theta) = G(\theta \sum_{j=1}^k y_j, \sum_{j=1}^k a_j, 1)$. This is the optimal CD for θ , and has **higher CD performance** than the Singh, Strawderman, Xie type

$$\tilde{C}(\theta) = \Phi\left(\sum_{j=1}^k w_j \Phi^{-1}(C_j(\theta))\right),$$

even for the optimally selected w_j .

Crucially, the **II-CC-FF strategy** is **very general** and can be used with **very different data sources** (e.g. **hard** and **soft** and **big** and **small** data). The potential of the **II-CC-FF paradigm** lies in its use for much more challenging applications (where each of **II**, **CC**, **FF** might be hard).

D1: Effective population size ratio for cod

A certain population of cod is studied. Of interest is both **actual population size** N and **effective population size** N_e (the size of a hypothetical stable population, with the same genetic variability as the full population, and where each individual has a binomially distributed number of reproducing offspring). The biological **focus parameter** in this study is $\phi = N_e/N$.

Steps II-CC for N : A CD for N , with confidence log-likelihood: A certain analysis leads to confidence log-likelihood

$$\ell_c(N) = -\frac{1}{2}(N - 1847)^2/534^2.$$

Steps II-CC for N_e : A CD for N_e , with confidence log-likelihood: This is harder, via genetic analyses, etc., but yields confidence log-likelihood

$$\ell_{c,e}(N_e) = -\frac{1}{2}(N_e^b - 198^b)/s^2$$

for certain estimated transformation parameters (b, s) .

Step FF for the ratio: A CD for $\phi = N_e/N$. This is achieved via log-likelihood profiling and median-Bartletting,

$$\ell_{\text{prof}}(\phi) = \max\{\ell_c(N) + \ell_{c,e}(N_e) : N_e/N = \phi\}.$$

D2: The Olympic unfairness of the 1000 m

Olympic **speedskaters** run the 1000 m in less than 70 seconds (speed more than 50 km/h). They skate two and a half laps, in pairs, with a **draw** determining inner/outer. **Acceleration** matters ($mv^2/r_1 > mv^2/r_2$ with $r_1 = 25$ m and $r_2 = 29$ m), and so does **fatigue** at end of race.

Start in inner lane: three inners, two outers.

Start in outer lane: two inners, three outers.

I shall estimate the **Olympic unfairness parameter** d , the difference between outer and inner, for top skaters.

In the Olympics: **only one race**. In the annual World Sprint Championships: they race 500 m and 1000 m both Saturday and Sunday, and they **switch start lanes**.

The six best men, from Calgary, January 2012, Saturday and Sunday, with 'i' and 'o' start lanes, and passing times:

		200 m	600 m	1000 m		200 m	600 m	1000 m	
1	Shani Davis	o	16.80	41.52	1:07.25	i	17.02	41.72	1:07.11
2	S. Groothuis	i	16.61	41.48	1:07.50	o	16.50	41.10	1:06.96
3	Kyou-Hyuk Lee	i	16.19	41.12	1:08.01	o	16.31	40.94	1:07.99
4	T.-B. Mo	o	16.57	41.67	1:07.99	i	16.27	41.54	1:07.99
5	M. Poutala	i	16.48	41.50	1:08.20	o	16.47	41.55	1:08.34
6	D. Lobkov	i	16.31	41.29	1:08.10	o	16.35	41.26	1:08.40

I **need a model** for (Sat, Sun) results (Y_1, Y_2), utilising passing times $u_{i,1}, v_{i,1}$ for Sat race and $u_{i,2}, v_{i,2}$ for Sun race, along with

$$z_{i,1} = \begin{cases} -1 & \text{if no. } i \text{ starts in inner on Saturday,} \\ 1 & \text{if no. } i \text{ starts in outer on Saturday,} \end{cases}$$

$$z_{i,2} = \begin{cases} -1 & \text{if no. } i \text{ starts in inner on Sunday,} \\ 1 & \text{if no. } i \text{ starts in outer on Sunday.} \end{cases}$$

to get hold of d .

My model for (Sat, Sun) results, for skater i :

$$Y_{i,1} = a_1 + bu_{i,1} + cv_{i,1} + \frac{1}{2}dz_{i,1} + \delta_i + \varepsilon_{i,1},$$
$$Y_{i,2} = a_2 + bu_{i,2} + cv_{i,2} + \frac{1}{2}dz_{i,2} + \delta_i + \varepsilon_{i,2}.$$

Here $u_{i,1}, u_{i,2}$ are 200 m passing time, $v_{i,1}, v_{i,2}$ are 600 m passing time; δ_i follows the skater, with $\delta_i \sim N(0, \kappa^2)$ across skaters; and $\varepsilon_{i,1}, \varepsilon_{i,2}$ are independent $N(0, \sigma^2)$. The inter-skater correlation is $\rho = \kappa^2 / (\sigma^2 + \kappa^2)$.

Crucially, outer lane start means adding $\frac{1}{2}d$, inner lane start means adding $-\frac{1}{2}d$, so d is overall difference due to start lane. Fairness means d should be very close to zero.

The model has seven parameters, and I need full analysis of dataset from each World Sprint Championships event to get hold of a CD for the focus parameter d .

From full analysis of World Sprint events 2014, ..., 2001 (seven parameters in each model), I get hold of

$$\hat{d}_j \sim N(d_j, \sigma_j^2),$$

and I then use $d_j \sim N(d_0, \tau^2)$. Full CD analyses are then available for d_0 and for τ .

Confidence curves $cc(d_j)$ for the fourteen unfairness parameters, over 2014 to 2001. The overall estimate 0.14 seconds (advantage inner-starter) is very significant, and big enough to make medals change necks.

Conclusion: The skaters need to run twice. (I've told the ISU.)

E: Concluding remarks (and further questions)

- a. If we have the raw data, and have the time and resources to do all the full analyses ourselves, then we would find the $C_j(\psi_j)$ in Step II = Independent Inspection. In real world we would often only be able to find a point estimate and a 95% interval for the ψ_j . We may still squeeze an approximate CD out of this.
- b. Step CC = Confidence Conversion is often tricky. There is no one-to-one correspondence between log-likelihoods and CDs. Data protocol matters. See CLP (2016).
- c. Step FF = Focused Fusion may be accomplished by profiling the combined confidence log-likelihood, followed by fine-tuning (Bartletting, median correction, abc bootstrapping).

d. Links to [Bayes and objective Bayes](#) – the II-CC-FF scheme can take on board an expert's prior for ψ_j alone, or for overall focus parameter $\phi(\psi_1, \dots, \psi_k)$, [without the full Bayesian job](#) (of having a joint prior for all parameters of all models).
